**Abstract.** Many practitioners and researchers advocate that the designs of the data models of the data warehouses should incorporate the source data as much as possible to answer the finest levels of queries. On the other hand, the source data are very likely to come from systems designed with ER Diagrams. Therefore, many researches have been devoted to design methodologies to build multidimensional model based on corresponding source ER diagrams. However, to the best of our knowledge, no algorithm has been proposed to systematically translates an entire ER Diagram into a multidimensional model with hierarchical snowflake structures. The algorithm proposed in the paper promised to do so with two characteristics, namely, grain preservation and minimal distance from each table to the fact table. Grain preservation characteristic guarantees that translated multidimensional model has cohesive granularity among entities. The minimal distance characteristics guarantees that if an entity can be connected to the fact table in the derived model with more than one paths, the one with the shortest hops will always be chosen. The first characteristic is achieved by translating problematic relationships between entities with weight factor attributes in bridging tables and enhancing fact tables with unique primary keys. The second characteristic is achieved by including a revised shortest path algorithm in the translating algorithm with the distance being calculated as the number of relationships required between entities.

## **1 Introduction**

As enterprizes worldwide strive to compete on real time management, providing valuable information in time to managers to help them perform timely decisions has become a critical mission for MIS departments in organizations worldwide. Among the related applications installed, data warehouses play a vital role for integrating, storing, and querying data. The data collected in data warehouses come from various transactional processing systems, such as, ERP, POS, etc. The collected data are cleaned, integrated and organized into structures designed for easy access and quick comprehension, for the purpose of decision making [\[11](#page-15-1), [12](#page-15-2)]. With its wide applications, many researches have been devoted to the study of proper models of data presentation [\[1](#page-14-0)[–5,](#page-14-1) [7](#page-15-3)[–10,](#page-15-4) [12,](#page-15-2) [13,](#page-15-5) [15](#page-15-6)[–21\]](#page-15-7). The dominant data model for representing a data warehouse is multidimensional modelling<sup>[1](#page-1-0)</sup>, also known as a *malposition* model, which is composed of a fact table in the center and a set of dimensional tables in the peripheral. The fact table stores measures of performance indicators which managers are interested to know and dimensional tables provide the viewpoints or entry points to view the data. A fact table and corresponding dimensional tables are linked by storing the primary keys of dimensional tables in the fact table. Figure [1](#page-1-1) is excerpted from [\[13\]](#page-15-5) and shows a sample multidimensional model with a fact table and three-dimensional tables. The grain is the level of detail at which measurements or events are stored [\[13](#page-15-5), [20\]](#page-15-8). To have cohesive querying results, the multidimensional models designed must have consistent grains, as pointed out by Inmon & Kimball [\[11](#page-15-1), [13](#page-15-5)]. After the grain is declared, all measures in the fact table and all dimension tables must adhere to the grain. Otherwise, unexpected query result may be returned. Following is an example of the grain mismatch. In a typical supermarket visit, customers may buy several products in one transaction and the dollar amount of each product is aggregated into a total. Given a multidimensional model recording the total dollar amount of each transaction, the grain is in the level of transaction. (shown in Figure [2\)](#page-2-0). If products are also stored as a dimension in the model, then querying the transaction amounts from product dimension will return figures that not only include amount of the product but also the amounts of other products purchased in the same transaction. The difference is due to the grain mismatch in the fact and the dimension table. The grain of the fact table is in transaction level, which may contains more than one products. Therefore, designing a model with coherent facts and dimensions is vital in designing multidimensional models.

**Fig. 1.** A Sample Multidimensional Model; source [\[13](#page-15-5)]

<span id="page-1-1"></span><span id="page-1-0"></span><sup>1</sup> Multidimensional model is also referred as dimensional model in some studies

<span id="page-2-0"></span>**Fig. 2.** The many-to-many relationship between the fact and dimension tables

On the other hand, data in a data warehouse are populated from source systems whose data probably are modeled by ER diagrams  $[6]$  $[6]$ . Therefore, the source ER diagrams show the most finest granular data that can be stored in a corresponding multidimensional model. If a systematic approach can be found to build multidimensional models to store data retrieved from the source systems modeled by ER diagrams, the work of model designers can be greatly reduced and more importantly, the errors committed can also be dramatically reduced.

Therefore, practitioners and researches have strived to propose methodologies to design multidimensional models from existing ER diagrams [\[3,](#page-14-3) [5](#page-14-1), [8,](#page-15-9) [9](#page-15-10), [14–](#page-15-11) [16,](#page-15-12) [19](#page-15-13)[–21\]](#page-15-7). Even though [\[12,](#page-15-2) [16,](#page-15-12) [20\]](#page-15-8) acknowledged the importance of grain consistence, they provide only vague guidelines for the mapping and do not specify any concrete algorithms to perform task. Moody and Kortink [\[16](#page-15-12)] proposed a threestep method,including classifying entities, identifying hierarchies and producing dimensional models, for developing a dimension model from entity relational models. They also presented five optional schemas in the paper, from simple flat schema to complex snowflake schema. Song et al.[\[20\]](#page-15-8) presented five methods to handle many-to-many relationships from an ERD to a dimension model. The possible solutions can be either adding a bridge table, denormalizing the dimensional table by positional-flag attributes or non-positional attribute, lowering the grain of the fact table to the dimension grain level, or lowering the grain of the fact table by separating data from the fact table.Bonifati et al. [\[4](#page-14-4)] presented a method to design a data mart. The method consists of three steps: top-down requirement analysis to elicit and consolidate user-requirements, bottom-up data model extract to form candidate data mart, and consolidation to derive the ideal data marts. Similarly, Cabibbo and Torlone [\[5\]](#page-14-1) proposed method to obtain a Multidimensional schema from an underlying operational databases. The schema consists of a finite set of dimensions, a finite set of F-tables, and a finite set of level descriptions of the dimensions. Golfarelli et al. [\[8](#page-15-9)] presented a graphical conceptual model (Dimensional Fact model) for data warehouses and a semi-automated methodology to construct a tree-structured fact schema from an Entity-Relation schema. Marotta et al. [\[15](#page-15-6)] provided a set of transformation rules to trace the mapping between source logical schema and data warehouse logical schema. Tryfona et al., [\[21\]](#page-15-7) presented a new model, the starER model, to make semantics richer than traditional multidimensional model to record manyto-many relationships between fact and dimensional tables.Boehnlein et al. [\[3](#page-14-3)] proposed the SERM model to visualize existence dependencies between data object types.

The approach proposed in the paper differs from the other approaches in following ways:

- (a) the algorithm systematically performs ER Diagrams to multidimensional model translation, given the fact table identified,
- (b) the algorithm guarantees that adding a new entity to the structure does not change the grain of existing entities,
- (c) the snowflake structure proposed by the algorithm takes the fewest relationship to connect dimensions and the given fact table.

The remainder of this paper is organized as follows:

Section [2](#page-3-0) formally defines grain preservations. Section [3](#page-4-0) presents the ER to multidimensional translation algorithm. Section [4](#page-9-0) explains how the two characteristics are achieved by the algorithm.

Section [5](#page-10-0) uses a case to demonstrate the algorithm. Finally, the summary and future work is presented in Section [6.](#page-13-0)

### <span id="page-3-0"></span>**2 Grain Preservation**

As Kimball pointed out [\[13\]](#page-15-5), a multidimensional model in general contains a fact table and a set of dimension tables. Each dimension table has a primary key which is also a foreign key of the fact table. The primary key of the fact table is the composition of all the foreign keys stored in the dimension tables.

If grain mismatch happens between the fact table and any of the dimension tables then the query result may be wrong [\[13,](#page-15-5) [20](#page-15-8)]. The erroneous queries return values that aggregate individual measures more than one time. Hence, a multidimensional model with the consistent grain should aggregate at most one copy of individual measure, regardless of the dimensions users querying along. Before formally defining grain preservation, we need to define two operators, namely,  $\sum$  and  $\star$ .

**Definition 1** *Given a table,* T, with m of its attributes are measures, namely,  $a_{i1}, \ldots, a_{im}$ , and n of its attributes are weight factors, namely,  $a_{j1}, \ldots, a_{jn}$ .

$$
\begin{aligned}\n& -\sum a_{ik} = \sum_{t \in T} t.a_{ik}, \text{ for } 1 \leq k \leq m \\
& -\sum(T) = \langle \sum a_{i1}, \dots, \sum a_{im} \rangle. \\
& -\star(T) = \{t'|\forall a \in attributes \text{ of } T, t \in T, \{a \notin \{a_{i1}, \dots, a_{im}\} \to t'.a = t.a\} \land \\
& (a \in \{a_{i1}, \dots, a_{im}\} \to t'.a = t.a \star t.a_{j1} \star \dots \star t.a_{jn})\}\n\end{aligned}
$$

With the  $\star$  operator, a measure can be refined to finer grain. Table [1](#page-4-1) shows a sample table with customer# as a non measure attribute, amount and cost as measures and weight  $factor_1$ , weight  $factor_2$  as weight factor attributes.

Table [2](#page-4-2) shows the result of applying  $\star$  operator on Table [1.](#page-4-1)

				$\vert$ customer# $\vert$ amount $\vert$ cost $\vert$ weight_factor <sub>1</sub> $\vert$ weight_factor <sub>2</sub> $\vert$
c125	50	30	.4	0.2
c125	50	30	$0.6\,$	$0.8\,$
c125	50		0.4	0.8
c125	50	30	0.6	0.2
c127	40			

<span id="page-4-1"></span>**Table 1.** A sample Table

<span id="page-4-2"></span>

				$\sqrt{\text{customer}}$   amount $\left  \text{cost} \right $ weight $\text{factor}_1$ weight $\text{factor}_2$
c125		2.4	0.4	$\rm 0.2$
c125	24		0.6	0.8
c125	16	9.6	0.4	0.8
c125		3.6	0.6	$0.2\,$
c127	40			

In a multidimensional model with snowflakes, a table can be added as a dimension table, which connects to the fact table directly, or as a table in the snowflake hierarchy, which is composed by a set of tables connected as a tree with the fact table as the root. A table added to a multidimensional model without breaking the existing grain provides an entry point to correctly summary measures.

<span id="page-4-3"></span>**Definition 2** *Given a multidimensional model with a fact table,* F*, and a table* T, if adding T to the multidimensional model results in a path of  $F, D_1, \ldots, D_k, T$ *connecting* T *to* F, and  $\sum (\star (F \bowtie D_1 ... \bowtie D_k \bowtie T)) = \sum (F)$ *, where*  $\bowtie$  *is a natural join operator then the addition is called* Grain Preservation*.*

## <span id="page-4-0"></span>**3 The Mapping Algorithm**

The section shows a relationship translation algorithm, which translates entities and relationships in an ER diagram to dimension tables in a multidimensional model while keeping grain preservations and taking the least join operators.

Given the ER diagram of a source system, the entities connecting to others with some many-to-many relationships and including additive numeric attributes are candidates for being the fact tables  $[12]$ . The paper assumes that a table in the source ER diagram is identified as the fact table which contains several fact attributes, also known as measures.

Given a source ER diagram with  $\langle E, R \rangle$ , where *E* is the set of entities and  $\mathbf{F}$ , the partial functions of relationships in the ER Diagram  $\mathbf{F} \cdot \mathbf{F} \times \mathbf{F} \rightarrow \mathbf{F}$ . *R* is the partial functions of relationships in the ER Diagram.  $R: E \times E \rightarrow \{1\}$  $1', '1-M', 'M-1', M-N'$ , where  $'1-1', '1-M', 'M-1'$  and  $'M-N'$  denote the cardinality of the relationships.

A multidimensional model is a  $\langle DE, DR \rangle$ , where *DE* is the set of tables in model, and *DR* is the partial function of relationships between the tables the model, and *DR* is the partial function of relationships between the tables. Every entity in *E*, and *DE* is assumed to have a primary key.

# <span id="page-5-1"></span>**3.1 Naive Mapping Rules**

The naive mapping rules analyze the *R* between entities in the source ER diagram and translate corresponding entities and relationships into multidimensional model. Translation of '1-M' and 'M-to-N' relationships may produce grain mismatch if they are not handled carefully. As pointed out in  $[12, 13, 20]$  $[12, 13, 20]$  $[12, 13, 20]$  $[12, 13, 20]$  $[12, 13, 20]$ , the mismatch can be corrected by lowering the grain in the fact tables or the grain in the dimension tables. In the case of snowflaked multidimensional model, we argue that lowering the grain of dimension tables should be more preferable since the same methodology can be applied to lower the grains of tables down in the snowflake hierarchy.

If  $\mathbf{R}(E_i, E_j)$  exists and  $E_i \in \mathbf{DE}$  then  $E_j$  is added to the  $\mathbf{DE}$  in following ways:

- Rule#1: 
$$
\mathbf{R}(E_i, E_j) = \text{M-to-1}
$$

- Rule#1:  $\mathbf{R}(E_i, E_j) = 'M\text{-to-1}'$ <br>In this case, the translation is straightforward.

$$
DE = DE \bigcup \{E_j\}
$$
  

$$
DR = DR \bigcup \{DR(E_i, E_j) = R(E_i, E_j)\}
$$

Figure [3](#page-5-0) shows an example of such cases.

Transformed in Relations

<span id="page-5-0"></span>**Fig. 3.** Transformation in a 'many-to-one' relationship

 $-$  Rule#2:  $R(E_i, E_j) = '1$ -to-M' Since the grain of  $E_i$  is finer than the grain of  $E_i$ , an attribute of weight factor is added to  $E_i$  to tune the grain of  $E_i$ .

$$
E'_{j} = E_{j} + \text{weight\_factor}
$$
  

$$
DE = DE \bigcup \{E'_{j}\}
$$
  

$$
DR = DR \bigcup \{DR(E_{i}, E'_{j}) = R(E_{i}, E_{j})\}
$$

Figure [4](#page-6-0) shows an example of '1-M' relationship translation.

**Transformed** in Relations

**Fig. 4.** Translation of a 'one-to-many' relationship

<span id="page-6-0"></span> $-$  Rule#3:  $R(E_i, E_j) = 'M$ -to-N'

Since The grains in the two tables are incompatible, a bridging table *B* is added to tune the grain. The table has two foreign keys coming from  $E_i$ , and  $E_i$ , respectively, and an attribute of weight factor  $[12, 20]$  $[12, 20]$  $[12, 20]$ . The foreign key from  $E_i$  groups entries in  $E_j$  so that the combinations of the entries have the same grains as the corresponding entries in the  $E_i$ . The attribute of weight factor records the contribution of the entries in the group. The summation of weight factor in each group should be equal to one.

$$
B = \langle weight\_factor \rangle
$$
  

$$
DE = DE \bigcup \{E_j, B\}
$$

$$
DR = DR \bigcup \{ DR(E_i, B) = '1 - to - M' \}
$$
  

$$
DR = DR \bigcup \{ DR(B, E_j) = 'M - to - 1' \}
$$

Figure [5](#page-7-0) shows such an example. The algorithm of transformation rules is shown in Figure [6.](#page-7-1)

<span id="page-7-1"></span>

## **3.2 Applying the Mapping Rules to an ER Diagram**

This section further explains the process of building an entire multidimensional model from a given source ER diagram. The algorithm proposed assume that a fact table in the source ER diagram has been identified and strives to find a multidimensional model with the least number of number of relationships.

Since an ER Diagram can be translated to more than one multidimensional model, the major decisions lie on the selection of relationships to form the translated multidimensional model. The point is illustrated by following example.

**Example 1** *An original ERD as shown in Figure [7\(](#page-8-0)A) that includes several loop relationships. A loop among the snowflake tables causes problems in aggregating measures when querying data. A loop means there are more than one path to join a given table in the loop to the fact table. The different path may aggregate measures differently and cause confusion. Therefore, loop in the given ER diagram has to be broken when translating the ER diagram into a multidimensional model.*

<span id="page-8-0"></span>**Fig. 7.** An example of the same ERD being transformed into different multidimensional models

 $\begin{array}{c} \text{radated} \ \text{3} \end{array}$ <br>  $\begin{array}{c} \text{chema-Fe} \ \text{multiid} \end{array}$ <br>  $\begin{array}{c} \text{in all } E. \ \text{are } ge \ \text{fferenc} \end{array}$ <br>  $\begin{array}{c} \text{are } ge \ \text{fferenc} \end{array}$ added E6 tide 2. ft e c in ( c ) c idea t t d =  $\frac{raded}{d}$  (C2) Stated<br>of different contract the order of  $\frac{sinh Bz}{c}$ <br>one was to use to the order of the order of  $\frac{sinh Bz}{c}$  and  $\frac{cosh Bz}{c}$  and  $\frac{$ 1) Pruned ERD-Format C (C2)<br>

podel. The paper propos *A loop can be broken in several ways. For example, the original ER diagram shown in*  $7(A)$  $7(A)$  *can be translated to two different ERDs (in Figure*  $7(B1)(C1)$ ). *Next, different multidimensional models (see Figure [7\(](#page-8-0)B2)(C2)) are generated by applying the naive mapping rules shown in section [3.1.](#page-5-1) The differences between the two figures are highlighted in circles.*

Hence, given an ER diagram, there are more than one way to build a corresponding multidimensional model. The paper proposes to use a shortest path algorithm to derive the multidimensional model where each entity has the shortest path to the fact table. The distances between entities and the fact table are counted by the number of relationships between them, since the more the relationships, the more join operators are needed to perform queries. Readers will find that the calculation of distances can be changed to many other formula, such as the estimated numbers of tuples participated in each join, without jeopardizing the integrity of the algorithm.

To compute the shortest distance between the fact table and all other tables, an initial distance matrix has to be built. The initial matrix is formed by scanning the entire ER diagram and for each entity pair that are connected by relationships other than 'M-to-N', the initial value of 'one' is assigned. For relationships that are 'M-to-N', an initial values of 'two' are assigned to the corresponding entries since a bridging table will be needed in the translation. After deriving the initial matrix, the algorithm then calculates the shortest path matrix, which is asymmetric. The diagonal elements are filled with zeros.

Zeros in diagonal entries of the distance matrix represent that the distance between an entity and itself is zero. Such an assumption may in contradiction to entities with self reference relationship in ER Diagrams. However, in the paper, the translated multidimensional model is assumed to be free of self reference relationships. The assumption is based on the widely adopted practice that most self reference relationships are flatten into corresponding entities to save query processing time. The algorithm of the Shortest Distance Computing is shown in Figure [8.](#page-10-1)

## <span id="page-9-0"></span>**4 Correctness Proof**

The section proves that given an ER diagram of  $\langle E, R \rangle$  with a fact table identified the algorithm of MR returns a *(DE DR)* which satisfies *Crain Preser*. tified, the algorithm of MR returns a  $\langle DE, DR \rangle$ , which satisfies *Grain Preser-*<br>*vation* in the process and all tables are connected to fact tables with the least *vation* in the process and all tables are connected to fact tables with the least relationships.

**Theorem 1** *Given an ER diagram and a fact table, the process of adding entities to*  $\langle$ *DE*, *DR* $\rangle$  *by algorithm MR is* Grain Preservation.

#### *Rationale*

*Only the addition of entities with relationships of '1-to-M' and 'M-to-N' may challenge grains of a multidimensional model. However, since the summary of weight factors in each group in the two cases have to equal to one, the grain is still be kept according to Definition [2.](#page-4-3)*

The fewer the relationships between entities and the fact table in a multidimensional model, the more efficient the queries issued from the entity can be processed.

**Theorem 2** *Given an ER diagram and a fact table, the multidimensional model discovered by algorithm MR connecting each entity to the fact table with the least number of relationships.*

Algorithm: Shortest Distance Input:  $E_0$  //the fact table  $\langle E,R \rangle$  //the original ERD Output *L*0: Initial Distance Matrix *L* : Shortest Distance Matrix Begin Fill  $L_0$  with  $\infty$ // scan the original ERD and assign initial value to each relationship for  $i=0$  to  $\mid E \mid$  do  $\mid$ for j=1 to  $\mid E \mid$  do { for each  $\mathbf{R}(E_i, E_j)$  do { if  $R(E_i, E_j) = 'M$ -to-1' then  $L_0(E_i, E_j) = 1$ elseif  $E(E_i, E_j) = '1$ -to-1' then  $L_0(E_i, E_j) = 1$ elseif  $\mathbf{R}(E_i, E_j) = \text{`1-to-M'}$  then  $\mathbf{L}_0(E_i, E_j) = 1$ elseif  $\mathbf{R}(E_i, E_j) = \text{`M-to-N'}$  then  $\mathbf{L}_0(E_i, E_j) = 2$ } } } //Computing shortest path matrix for  $i = 0$  to  $|E|$  { for  $j = 0$  to  $|E|$  { for  $k = 0$  to  $|E|$  {  $L(E_j, E_k) = \min(L(E_j, E_k), L(E_j, E_i) + L(E_i, E_k))$ } } } return  $L_0, L_1$ End;

<span id="page-10-1"></span>**Fig. 8.** Computing the Shortest Distance Between Entities and the Fact Table

#### *Rationale*

*The distances between entities to the fact table are computed by the relationships needed to connect the two tables. MR adds only one relationship to the multidimensional model when needed, which is the most efficient way found up to date [\[20](#page-15-8)] when keeping the grains of fact tables are mandatory. Besides, the MR algorithm uses the shortest path algorithm to find the paths with the least relationships to connect entities with the designated fact table.*

## <span id="page-10-0"></span>**5 A Sample Case**

In order to show the translation process, a sample is demonstrated in the section. Figure [9\(](#page-11-0)a) shows a sample ER Diagram derived from a commercial sales order tracking system. The designated fact table is the order table. With several loops in the ER diagrams, the diagram can be translated into more than one multidimensional model. The initial distance between connected entities are marked in

Table 3. the shortest distance matrix from entity Order to other entities

The algorithm MR is then applied to translate selected relationships and corresponding entities into a multidimensional model. The transformation process is illustrated in the following steps and also shown in Figure [10:](#page-13-1)

- (a) The designated fact entities *Order* is added into *DE* (identified as Step 1 in Figure [10\)](#page-13-1).
- (b) Based on the elements in the first row in the shortest distance matrix to transform relationships. Entity *Return, Invoice, Shipment, Customer, Promot Store, Store*, and *Data warehouse* are candidates since their distances to Entity *Order* are the shortest. Assuming Entity *Return* is processed first. Since the relationship between *Return* and *Order* is one-to-many; a weight factor attribute is added into *Return*. *Return* is added into *DE* and the *<sup>R</sup>*(*Order*, *Return*) is added to *DR* (identified as Step 2 in Figure [10\)](#page-13-1).
- (c) With the addition of Entity *Return* to *DE*, the eligible entities becomes Entity *Invoice, Shipment, Customer, Prmot Store, Store*. Assuming *Invoice* is processed next. Since the relationship between *Invoice* and *Order* is manyto-one, the *Invoice* dimension in added into *DE* and the relationship of *<sup>R</sup>*(*Order*,*Invoice*) is added to *DR* (identified as Step 3 in Figure [10\)](#page-13-1).
- (d) Entities *Shipment*, *Promot Store*, *Customer* and *Store* are added to the model as in previous steps (identified as Step 4 through Step 7 in Figure [10\)](#page-13-1).
- (e) Entity *Product* is processed then, the relationship between *Product* and *Order* is many-to-many; a bridge table *Prod\_B* with a weight factor attribute will be added in between to tune the grain, the relationships of *<sup>R</sup>*(*Order*,*Prod <sup>B</sup>*) and *<sup>R</sup>*(*Prod <sup>B</sup>*,*Product*) are added to *DR* (identified as Step 8 in Figure [10\)](#page-13-1).

**Fig. 10.** The Translated multidimensional model  $\langle DE, DR \rangle$ 

- <span id="page-13-1"></span>(f) With addition of all entities in level one, Entity *Logistics*, *Promot type*, *Area*, *Warehouse* and *Supplier* are becoming eligible to be processed next. Entity *Logistics*, *Promot type*, *Area*, *Warehouse* are process as entity *Invoice* done in Step 5 (identified as Step 9 through Step 12 in Figure [10\)](#page-13-1).
- (g) Finally, Entity *Supplier* is processed, the transformation process is same as Entity *Product*; thus, a bridge table *Supp B* is added into *DE* and two relationships *<sup>R</sup>*(*Product*, *Supp <sup>B</sup>*) and *<sup>R</sup>*(*Supp <sup>B</sup>*, *Supplier*) are added to *DR* (identified as Step 13 in Figure [10\)](#page-13-1).

### <span id="page-13-0"></span>**6 Summary and Conclusions**

As enterprizes place top priority on real time management, Data Warehouse systems have become critical information analytical tools. However, most companies suffer from the lack of experienced Data Warehouse design professionals to effectively design multidimensional models. On the contrary, people with ERD concepts and experiences are far more widely available. Hence, deriving data warehouse schema from ER diagram may be one of the best way to create multidimensional models. However, a corporate Data Warehouse is not easy to be built by inexperienced Data Warehouse team in a short time. The techniques and mapping rules presented here will be valuable for them to have a quick and correct start. This paper presents a tool to derive data warehouse schema from ER diagrams. The transformation rules presented in this paper give Data Warehouse team a great tool to start with.

The main contribution of this paper providing an efficient and correct algorithm to translate ER diagrams into multidimensional model. The algorithm is efficient because every dimension table in the formed proposed hierarchy is connected to the fact table through the least expensive path. The algorithm is correct in that while adding new entities to existing multidimensional models, it still preserves the grain of the original dimensional model.

The issue of data warehouse model design should also include user requirement taking, verification and integration of the requirement with atomic grain data. Therefore, the work presented in this paper is just a foundation for further research of systematic data warehouse schema design.
